Submitted in partial fulfillment of the requirements for the MSc degree in Computing Science of Imperial College London

September 2016

**Abstract**

Implementing exception handling in Haskell. Unlike other libraries, use named exception handlers. Use the $\lambda^{\text{try}}$-calculus to formalize and explore a series of translations between multiple calculi to arrive at a translation into Haskell. Explore properties of this translation including soundness and completeness. Publish useable Haskell library.

# 1 | Introduction

Explanation of problem space: need and motivation demonstrated with examples.

## Solution

## Contribution

# 2 | Background

This chapter explores what *formal systems* are and what they are useful for. It looks at a number of related formal systems and their relation to computation. It outlines context ontop of which the rest of this project is built.

## $\lambda$-Calculus

Description of $\lambda$-calculus: what why and who?

### Syntax

$\lambda$-variables are represented by $x, y, z, x', y', \&c$. Variables denote an arbitrary value: they do not describe what the value is but that any two occurrences of the same variable represent the same value. The grammar for constructing well-formed $\lambda$-terms is:

**Definition 2.0.1** (Grammar for untyped $\lambda$-calculus)

$\lambda$-variables are denoted by $x, y, \ldots$

$$M, N \quad ::= \quad x \mid \lambda x.M \mid M\ N$$

$\lambda$-abstractions are represented by $\lambda x.M$ where $x$ is a parameter and $M$ is the body of the abstraction. The same idea is expressed by more conventional notation as a mathematical function $f(x) = M$. The $\lambda$ annotates the beginning of an abstraction and the . separates the parameter from the body of the abstraction. This syntax is inductive meaning the body is just another term constructed using the same rules. Some examples of abstractions are:

Applications are represented by any two terms, constructed according to the grammar, placed alongside one another. Application gives highest precedence to the leftmost terms. Bracketing can be introduced to enforce alternative application order for example $xyz$ is implicitly read as $(xy)z$ but an be written as $x(yz)$ to describe that the application of $yz$ should come first. Examples of applications are:

$\lambda x.x$
$\lambda x.y$
$\lambda x.(\lambda y.xy)$

Figure 2.1: Examples of valid $\lambda$-abstractions

$xy$
$xyz$
$x(yz)$
$(\lambda x.x)y$

Figure 2.2: Examples of valid applications

## Reduction Rules

First we will introduce the substitution notation $M[N/x]$. This denotes the term M with all occurrences of x replaced by N. The substitution notation is defined inductively as:

**Definition 2.0.2** (Substitution notation for $\lambda$-terms)

$$\begin{array}{rcll} x[y/x] & \rightarrow & y & \\ z[y/x] & \rightarrow & z & (z \neq x) \\ (\lambda z.M)[y/x] & \rightarrow & \lambda z.(M[y/x]) & \\ (MN)[y/x] & \rightarrow & M[y/x]N[y/x] & \end{array}$$

The main derivation rule of the $\lambda$-calculus is $\beta$-reduction. If term $M$ $\beta$-reduces to term $N$, we write $M \rightarrow_\beta N$ although the $\beta$ subscript can be omitted if it is clear from context. $\beta$-reduction is defined for all $\lambda$-terms: It

**Definition 2.0.3** ($\beta$-reduction rules for $\lambda$-calculus)

$$\begin{array}{rcl} x & \rightarrow_\beta & x \\ \lambda x.M & \rightarrow_\beta & \lambda x.M \\ (\lambda x.M)N & \rightarrow_\beta & M[N/x] \end{array}$$

is evident from the rules in Definition 2 that variables and abstractions $\beta$-reduce to themselves. Only applications reduce to other terms. This means that an application is a reducible expression or a *redex*.

Reducing a *redex* models the running of a function. It is $\beta$-reduction that provides the $\lambda$-calculus with the ability to model computation.

### Reduction Strategies

## Continuations

Compound terms can be decomposed into two seperate parts: a dominant term and a context. The dominant term is the term currently being evaluated. The context is a term with a hole that will be filled with the value the dominant term reduces to.

Assume that $M \rightarrow_\beta M'$

| | | | |
|---|---|---|---|
| *(Compound term)* | | $MN$ | |
| *(Decompose)* | $M$ | | $\Box N$ |
| *(Beta-reduce dominant term)* | $M'$ | | $\Box N$ |
| *(Refill hole of context)* | | $M'N$ | |

Figure 2.3: Decomposing a term into a dominant term and a context

When $M$ has $\beta$-reduced to $M'$ then the hole of the context $\Box N$ is filled to form $M'N$. What the dominant term and context are for a given term depends on the reduction rules and strategy. The context is what remains to be reduced at given moment of reduction. Thus a context is also called a *continuation*.

### Undelimited Continuations

For more complex terms, the waiting context will grow as the dominant term gets further decomposed:

| | |
|---|---|
| $(MM')M''$ | |
| $(MM')$ | $\Box M''$ |
| $M$ | $(\Box M')M''$ |

Figure 2.4: Decomposing a term into multiple contexts

By amalgamating continuatinos into one, big continuation we only have two components at point during the reduction: the current dominant term and the *current continuation*.

Assume we have some control operations defined for manipulating continuations. With this model, these operations would only be able to control the entire remaining continuation. That is to say we can only return values to the entire continuation and not to arbitrary parts of it. For this reason, continuations that can only be manipulated in their entirety are **undelimited continuations**.

### Delimited-Continuations

For complex terms, we can instead maintain continuations of continuations:

$$\begin{array}{lll} (MM')M'' & & \\ (MM') & \Box M'' & \\ M & \Box M' & \Box M'' \end{array}$$

Figure 2.5: Decomposing a term into multiple contexts

Here, we have a stack of remaining continuations. When a dominant term has been reduced, the reduct is returned to its corresponding continuation. This newly joined term then becomes the dominant redex. After this new dominant term has been reduced, it will be returned to the next waiting continuation, and so on. Throughout this process, we maintain each continuation separately.

Assume again that we have operations defined for manipulating continuations. This model would allow use to control different combinations of continuations. The increased granularity of control means we can control not just the entire remaining context but parts of it. Thus, continuations of this kind are called **delimited continuations**.

### Continuation-Passing Style

Continuations are what is left of the computation. By rewriting $\lambda$-terms, continuations can be made explicit. All terms must be turned into $\lambda$-abstractions of $k$ where $k$ is the continuation of a term. $k$ is then called on the result of the term, triggering the continuation to take control. This style of writing $\lambda$-terms is called continuation-passing style or CPS.

**Definition 2.0.4** (Semantics for continuation-passing style)

$$\begin{array}{lcc} \underline{x} & = & \lambda k.kx \\ \underline{\lambda x.M} & = & \lambda k.k(\lambda x.\underline{M}) \\ \underline{MN} & = & \lambda k.M(\lambda m.m\underline{N}(\lambda n.mnk) \end{array}$$

The term that a CPS program terminates on will be of the form $\lambda k.kM$. In order to extract the value, a *final continuation* must be provided. Depending on the context, this is likely to be an identity function $\lambda x.x$ or a display operation $\lambda x.$display $x$ to display the results of the program.

The translation of standard $\lambda$-terms into CPS similarly transforms the *types* of $\lambda$-terms. For example, a term $x : A$ becomes $\lambda k.kx : (A \to B) \to B$. This type represents a delayed computation: a computation that is waiting for a function to continue execution with. In order to resume the computation, the term must be applied to a continuation.

As an example, take the term M where

$$M = \lambda k.k(\lambda y.fy)$$

To apply the abstraction contained in $M$, we have to apply $M$ to a continuation function $\lambda m.N$:

$$(\lambda k.k(\lambda y.fy))(\lambda m.N)$$
$$(\lambda m.N)(\lambda y.fy)$$
$$N[\upsilon.fy/m]$$

Within the body of $N$, $m$ is bound to the value contained by $M$. So we can think about $M$ as a suspended computation that, when applied to a continuation, applies the continuation to $\lambda.fy$. Looking at the type $(A \to B) \to B$ again, it is clear that $A$ is the type of the term passed to a CPS-term's continuation:

$$\lambda k.kx : (A \to B) \to B$$
$$k : (A \to B)$$
$$kx : B$$
$$x : A$$

## Monads

If we have two suspended computations $M$ and $M'$ and we want to run $M$ and then $M'$, we have to apply $M$ to a continuation to access its value and then do the same to $M'$:

$$M(\lambda m.M'(\lambda m'.N))$$

This is a common operation so we define a utility operator `>>=` that binds the first suspended computation to a continuation which returns another suspended computation:
[1]

$$\texttt{>>=} : ((A \to B) \to B) \to (A \to ((B \to C) \to C)) \to ((B \to C) \to C)$$

The type $(A \to B) \to B$ that represents a suspended computation returning a value of type $A$ to its continuation we will call an $A$-computation or $Comp\ A$. We can rewrite the type signature of `>>=`:

$$\texttt{>>=} : Comp\ A \to (A \to Comp\ B) \to Comp\ B$$

We define another operator, *return*, that takse a value and returns a suspended computation that returns that value:

[1] `(>>=)` is pronounced 'bind'.

$$return : A \to Comp\ A$$

The type constructor $Comp\ A$, together with the two utility functions `>>=` and *return*, make up Haskell's Monad type class:

```
class Monad M where
  (>>=) :: M a -> (a -> M b) -> M b
  return :: a -> M a
```

The Monad type class generalizes CPS terms: they represent suspended computations that can be composed using `>>=`.

Haskell has an infix operator for function application called `$`. The operator has the type signature `(a -> b) -> a -> b`. This is the operator for function application. For instance we can take a function `addOne :: Int -> Int` and write:

```
($) :: (a -> b) -> a -> b
intToString :: Int -> String
($) intToString :: Int -> String
($) intToString 4 :: String
```

If we preapply `$` to an argument `x :: a` then the resulting term will be `($ x) :: (a -> b) -> b`. We can read `($ x)` as a function that takes an argument $f$ and applies $f$ to $x$. It is a term waiting for a function. This is the same type as CPS terms:

$$M : B$$
$$\lambda k.kM : (A \to B) \to B$$

A term with type $(A \to B) \to B$ represents a suspended computation. When the computation is passed a function with which to continue, the computation will return a value of type $B$. We will call this a $B$-computation or $Comp\ B$ for short. If we have a term of type $Comp\ B$, we have a term that requires a function.

# $\lambda\mu$-Calculus

## Syntax

Just as $\lambda$ introduces a new $\lambda$-abstraction, $\lambda\mu$ introduces a new $\lambda\mu$-abstraction. The body of a $\lambda\mu$-abstraction must be a named term. A named term consists of a name of the form $[\alpha]$ followed by an unnamed term.

**Definition 2.0.5** (Grammar for $\lambda\mu$-calculus)

$\lambda$-variables are denoted by $x, y, \ldots$ and $\mu$-variables are denoted by $\alpha, \beta, \ldots$

$$\begin{array}{lrcl} \text{(Unnamed term)} & M, N & ::= & x \mid \lambda x.M \mid M\ N \mid \mu\alpha.C \\ \text{(Named term)} & C & ::= & [\alpha]M \end{array}$$

**Definition 2.0.6** (Reduction rules for $\lambda\mu$-calculus)

$$\begin{array}{rcl} x & \rightarrow & x \\ \lambda x.M & \rightarrow & \lambda x.M \\ \mu\alpha.[\beta]M & \rightarrow & \mu\alpha.[\beta]M \\ (\lambda x.M)N & \rightarrow & M[N/x] \\ (\mu\alpha.[\beta]M)N & \rightarrow & (\mu\alpha.[\beta]M[[\gamma]M'N/[\alpha]M']) \end{array}$$

## Reduction Rules

The terse reduction rule at the end simple states that the application of a $\lambda\mu$-abstraction $\mu\alpha.M$ to a term $N$ applies all the sub-terms of $M$ labelled $[\alpha]$ to $N$ and relabels them with a fresh $\mu$ variable.

## Computational Significance

The additional $\lambda\mu$ reduction rules model context manipulation. $\lambda\mu$-variables map to contexts. When an unnamed term is labelled with a $\lambda\mu$-variable, it is evaluated in that context. For instance the named term $['a]M$ has the effect of evaluating $M$ in the context pointed to by $\alpha$.

To make this more concrete, consider the compound term $(\mu\alpha.[\beta]M)\ N$. First we decompose the term into a dominant term $(\mu\alpha.[\beta]M)$ and a context $\Box N$. Informally, we can imagine that the $\lambda\mu$-variable $\alpha$ now maps to this context $\{\alpha \Rightarrow \Box N\}$:

*Example 2.0.7*

| **Dominant** | **Context** |
|---|---|
| $(\mu\alpha.[\beta]M)N$ | |
| $\mu\alpha.[\beta]M$ | $\Box N$ |

All subterms of $M$ labelled $\alpha$ will now be evaluated in the context $\Box N$ and the context will destroyed. For example, let us replace $M$ with $\mu \circ .[\alpha](\lambda s.fs)$:

*Example 2.0.8*

| **Dominant** | **Context** | |
|---|---|---|
| $\mu\alpha.[\beta]\mu \circ .[\alpha](\lambda s.fs)$ | $\Box N$ | |
| $\mu\alpha.[\alpha](\lambda s.fs)$ | $\Box N$ | |
| $\mu\gamma.[\gamma](\lambda s.fs)N$ | | ($\gamma$ fresh) |

After applying the term $[\alpha](\lambda s.fs)$ to $N$, the context $\Box N$ is consumed and every occurrence of $\alpha$ is replaced with a fresh variable – in this case a $\gamma$ – to clarify that the new $\lambda\mu$-abstraction points to a new context. This means that $\lambda\mu$-abstractions will pass all of the applicative contexts to the named subterms:

*Example 2.0.9*

| **Dominant** | **Context** | |
|---|---|---|
| $(\mu\alpha.[\alpha](\lambda s.\lambda t.st))MN$ | | |
| $(\mu\alpha.[\alpha](\lambda s.\lambda t.st))M$ | $\Box N$ | |
| $\mu\alpha.[\alpha](\lambda s.\lambda t.st)$ | $\Box M : \Box N$ | |
| $\mu\gamma.[\gamma](\lambda s.\lambda t.st)M$ | $\Box N$ | ($\gamma$ fresh) |
| $\mu\delta.[\delta](\lambda s.\lambda t.st)MN$ | $\Box N$ | ($\delta$ fresh) |

### Isomorphism & Computational Interpretation

## $\lambda^{\text{try}}$-Calculus

## Delimited-Continuation Calculus

Simon Peyton-Jones *et al.* extended the $\lambda$-calculus with additional operators in order create a framework for implementing delimited continuations [1]. This calculus will be referred to as the delimited-continuation calculus or DCC. Many calculi have been devised with control mechanisms. Like the $\lambda\mu$-calculus, these control mechanisms are all specific instances of delimited and undelimited continuations. DCC provides a set of operations that are capable of expressing many of these other common control mechanisms.

The grammar of DCC is an extension of the standard $\lambda$-calculus:

### Syntax

### Reduction Rules

The operational semantics can be understood through an abstract machine that transforms tuple of the form $\langle e,\ D,\ E\,q\rangle$:

**Definition 2.0.10** (Grammar for DCC)

$$
\begin{array}{lrcl}
\text{(Variables)} & x, y, \ldots & & \\
\text{(Expressions)} & e & ::= & x \mid \lambda x.e \mid e\ e' \\
& & \mid & \mathit{newPrompt} \mid \mathit{pushPrompt}\ e\ e \\
& & \mid & \mathit{withSubCont}\ e\ e \mid \mathit{pushSubCont}\ e\ e
\end{array}
$$

**Definition 2.0.11** (Operational semantics for DCC)

$$
\begin{array}{lcll}
\langle e\ e', D, E, q\rangle & \Rightarrow & \langle e, D[\Box\ e'], E, q\rangle & \text{e non-value} \\
\langle v\ e, D, E, q\rangle & \Rightarrow & \langle e, D[v\ \Box], E, q\rangle & \text{e non-value} \\
\langle \mathit{pushPrompt}\ e\ e', D, E, q\rangle & \Rightarrow & \langle e, D[\mathit{pushPrompt}\ \Box\ e'], E, q\rangle & \text{e non-value} \\
\langle \mathit{withSubCont}\ e\ e', D, E, q\rangle & \Rightarrow & \langle e, D[\mathit{withSubCont}\ \Box\ e'], E, q\rangle & \text{e non-value} \\
\langle \mathit{withSubCont}\ p\ e, D, E, q\rangle & \Rightarrow & \langle e, D[\mathit{withSubCont}\ p\ \Box], E, q\rangle & \text{e non-value} \\
\langle \mathit{pushSubCont}\ e\ e', D, E, q\rangle & \Rightarrow & \langle e, D[\mathit{pushSubCont}\ \Box\ e'], E, q\rangle & \text{e non-value}
\end{array}
$$

$$
\begin{array}{lcl}
\langle (\lambda x.e)\ v, D, E, q\rangle & \Rightarrow & \langle e[v/x], D, E, q\rangle \\
\langle \mathit{newPrompt}, D, E, q\rangle & \Rightarrow & \langle q, D, E, q+1\rangle \\
\langle \mathit{pushPrompt}\ p\ e, D, E, q\rangle & \Rightarrow & \langle e, \Box, p : D : E, q\rangle \\
\langle \mathit{withSubCont}\ p\ v, D, E, q\rangle & \Rightarrow & \langle v(D : E\overset{p}{\uparrow}, \Box, E\overset{p}{\downarrow}, q\rangle \\
\langle \mathit{pushSubContE'}\ e, D, E, q\rangle & \Rightarrow & \langle e, \Box, E' + +(D : E), q\rangle
\end{array}
$$

$$
\begin{array}{lcl}
\langle v, D, E, q\rangle & \Rightarrow & \langle D[v], \Box, E, q\rangle \\
\langle v, \Box, p : E, q\rangle & \Rightarrow & \langle v, \Box, E, q\rangle \\
\langle v, \Box, D : E, q\rangle & \Rightarrow & \langle v, D, E, q\rangle
\end{array}
$$

## Significance

The additional terms behave as follows:

- *newPrompt* returns a new and distinct prompt.
- *pushPrompt*'s first argument is a prompt which is pushed onto the continuation stack before evaluating its second argument.
- *withSubCont* captures the subcontinuation from the most recent occurrence of the first argument (a prompt) on the excution stack to the current point of execution. Aborts this continuation and applies the second argument (a $\lambda$-abstraction) to the captured continuation.
- *pushSubCont* pushes the current continuation and then its first argument (a subcontinuation) onto the continuation stack before evaluating its second argument.

# 3 | DCC Interpreter

This chapter explores the implementation of an interpreter for DCC. Portions of source code are examined in detail although the full source can be found in the appendix.

## Interpreter

Although Peyton-Jones *et al.* implement a language-level module for DCC, we are interested in the intermediate term transformations. Examining transformation steps in full allows us to derive proofs of soundness and completeness for the translations from the $\lambda$ and $\lambda\mu$ calculi into DCC. For this reason, the interpreter was implemented as a term-rewriting program.

Whereas the original grammar for the DCC abstract machine presents sequences as values, the original exposition leaves the semantics for transforming sequences into useable expressions implicit. These semantics are unpacked in the implementation details. To capture the correct behaviour in this interpreter, we must formalize these semantics as a syntax-transformation. Sequences are therefore presented as expressions with the following explicit reduction rule:

**Definition 3.0.1** (Semantics of a sequence of continuations)
Let $D_i$ denote some term with a hole and $D_i[v]$ denote the term $D_i$ with the hole filled by $v$:

$$\langle (D_1 : D_2 : \cdots : D_n), D', E, q \rangle \quad \Rightarrow \quad \langle \lambda x.D_n[D_{n-1}[\, \ldots D_1[x] \ldots ]], D', E, q \rangle$$

A sequence of contexts evaluates to an abstraction that, when applied to a value $v$, returns $v$ to the first context which returns its value to the second context and so on through the whole sequence.

# Implementation

## Data structures

There are two data types for representing DCC terms, `Value` and `Expr`:

```
data Value
  = Var Char
  | Abs Char Expr
  | Prompt Int

data Expr
  = Val Value
  | App Expr Expr
  | Hole
  | PushPrompt Expr Expr
  | PushSubCont Expr Expr
  | WithSubCont Expr Expr
  | NewPrompt
  | Seq [Expr]
  | Sub Expr Expr Char
```

The core of the abstract machine is a function from one state to the next. A state is its own data type which corresponds to the tuple from the specification of the semantics of the abstract machine $\langle e,\ D,\ E,\ q \rangle$:

```
data State
  = State Expr Expr [Expr] Value
```

## Utility Functions

Some utility functions are defined to help readability. See Figure 3 for implementations:

- `prettify :: Expr -> String` is defined inductively for pretty-printing terms.
- `ret :: Expr -> Expr -> Expr` returns the first expression with any holes filled in by the second expression.
- `contextToAbs :: Expr -> Expr` takes a term with a hole and returns an abstraction that fills the hole with an expression when applied to it.
- `seqToAbs :: [Expr] -> Expr` takes a sequence of expressions and, starting from the end, fills the hole of each expression with the previous expression. This in effect joins the output of each context with the

input of the next context. It then turns this large context into an abstraction using `contextToAbs`.

- `promptMatch :: Int -> Expr -> Bool` returns true if the second argument is a Prompt and has the same value as the first argument
- `splitBefore :: [Expr] -> Int -> [Expr]`
- `splitAfter :: [Expr] -> Int -> [Expr]`
- `sub :: [Expr] -> Int -> [Expr]`

### Reduction Rules

The heavy lifting is done by the function `eval :: State -> State`. `eval` is defined inductively on the structure of the current expression. Each case of `eval` corresponds directly to at least one of the reduction rules of the DCC operational semantics. The full source can be found in the appendix:

The first case deals with applications of the form `e e'`. If both terms are values and the first term is an abstraction of the form $\lambda$`x.m`, the dominant term becomes a substitution of `e'` for `x` in `m`. Otherwise, the term that is a redex is made the dominant term and the remainder of the application is added to the current context. If both terms are redexes, the left-most is made the dominant first. In effect, an application first ensures the left-hand term has been evaluated fully before evaluating the right-hand term.

```
eval (State (App e e') d es q) = case e of
  Val v -> case e' of
    Val _ -> case v of (Abs x m) -> State (Sub m e' x) d es q
    otherwise -> State e' (ret d (App e Hole)) es q
  otherwise -> State e (ret d (App Hole e')) es q
```

This implements the following three reduction rules:

$$\begin{array}{lcll} \langle e\ e', D, E, q\rangle & \Rightarrow & \langle e, D[\Box\ e'], E, q\rangle & \text{e non-value} \\ \langle v\ e, D, E, q\rangle & \Rightarrow & \langle e, D[v\ \Box], E, q\rangle & \text{e non-value} \\ \langle (\lambda x.e)\ v, D, E, q\rangle & \Rightarrow & \langle e[v/x], D, E, q\rangle & \end{array}$$

The following reduction rules for pushPrompt are implemented to ensure the first expression has been evaluated to a prompt:

$$\begin{array}{lcl} \langle pushPrompt\ e\ e', D, E, q\rangle & \Rightarrow & \langle e, D[pushPrompt\ \Box\ e'], E, q\rangle \\ \langle pushPrompt\ p\ e, D, E, q\rangle & \Rightarrow & \langle e, \Box, p : D : E, q\rangle \end{array}$$

```
eval (State (PushPrompt e e') d es q) = case e of
  Val _ -> State e' Hole (e:d:es) q
  otherwise -> case d of
    Hole -> State e (PushPrompt Hole e') es q
    otherwise -> State e (ret d (PushPrompt Hole e')) es q
```

```
contextToAbs e = (Val (Abs fresh body))
  where fresh = 'x'  -- TODO: generate truly fresh var
        body = ret e (Val (Var fresh))

ret d e = case d of
  Hole -> e
  App m n -> App (ret m e) (ret n e)
  Val (Abs x m) -> Val $ Abs x (ret m e)
  PushPrompt m n -> PushPrompt (ret m e) (ret n e)
  WithSubCont m n -> WithSubCont (ret m e) (ret n e)
  PushSubCont m n -> PushSubCont (ret m e) (ret n e)
  otherwise -> d

seqToAbs es = contextToAbs $ foldr ret Hole $ reverse es

sub m v x = case m of
  Val (Var n) -> if n == x then v else m
  Val (Abs y e) -> Val (Abs y $ sub e v x)
  Val (Prompt p) -> Val (Prompt p)
  App e e' -> App (sub e v x) (sub e' v x)
  NewPrompt -> NewPrompt
  PushPrompt e e' -> PushPrompt (sub e v x) (sub e' v x)
  WithSubCont e e' -> WithSubCont (sub e v x) (sub e' v x)
  PushSubCont e e' -> PushSubCont (sub e v x) (sub e' v x)

promptMatch i p = case p of
  (Val (Prompt p')) -> i == p'
  otherwise -> False

splitBefore p es = takeWhile (not . promptMatch p) es

splitAfter  p es = case length es of
  0 -> []
  otherwise -> tail list
  where list = dropWhile (not . promptMatch p) es
```

Figure 3.1: Utility functions for DCC interpreter

The reduction rules for `WithSubCont` ensure that the first argument has been evaluated to a prompt `p` and then that the second argument has been evaluated to an abstraction. Finally, it appends the current continuation to the sequence yielded by splitting the continuation stack at `p`, and creates an

application of the second argument to this sequence.

$$\begin{array}{lcl} \langle withSubCont\ e\ e', D, E, q\rangle & \Rightarrow & \langle e, D[withSubCont\ \square\ e'], E, q\rangle \\ \langle withSubCont\ p\ e, D, E, q\rangle & \Rightarrow & \langle e, D[withSubCont\ p\ \square], E, q\rangle \\ \langle withSubCont\ p\ v, D, E, q\rangle & \Rightarrow & \langle v(D : E\overset{p}{\uparrow}, \square, E\overset{p}{\downarrow}, q\rangle \end{array}$$

```
eval (State (WithSubCont e e') d es q) = case e of
  Val v -> case e' of
    Val _ -> case v of
      (Prompt p) -> State (App e' (Seq (d:beforeP))) Hole afterP q
                    where beforeP = splitBefore p es
                          afterP = splitAfter p es
    otherwise -> State e' (ret d (WithSubCont e Hole)) es q
  otherwise -> State e (ret d (WithSubCont Hole e')) es q
```

Reducing `PushSubCont` ensures that the first argument is a sequence, pushes the current continuation onto the stack, and then pushes the abstraction that represents the sequence onto the stack. The abstraction is first applied to a Hole. This is a hack to reverse the conversion of context-sequences into abstractions. This is necessary because context-sequences need to be abstractions when being applied but need to be sequences when being composed with other sequences of contexts.

```
eval (State (PushSubCont e e') d es q) = case e of
  Val v -> State e' Hole ([App (Val v) Hole]++(d:es)) q
  otherwise -> State e (ret d (PushSubCont Hole e')) es q
```

The reduction of `Sub` states is defined inductively on the structure of the first argument of dominant term. The base case replaces matching variables with the second term. The other cases ensure that substitution is propogated to the subterms.

```
eval (State (Sub e y x) d es q) =
  State e' d es q
  where e' = case e of
          Val (Var m) -> if m == x then y else (Val (Var m))
          Val (Abs h m) -> Val (Abs h (sub m y x))
          App m n -> App (sub m y x) (sub n y x)
          Val (Prompt p) -> Val (Prompt p)
          NewPrompt -> NewPrompt
          PushPrompt e1 e2 -> PushPrompt (sub e1 y x) (sub e2 y x)
          WithSubCont e1 e2 -> WithSubCont (sub e1 y x) (sub e2 y x)
          PushSubCont e1 e2 -> PushSubCont (sub e1 y x) (sub e2 y x)
```

Evaluating a `Seq` transforms the sequence into an abstraction using `seqToAbs`. This corresponds to the reduction rule we introduced in Figure 3:

```
eval (State (Seq s) d es q) =
  State (seqToAbs s) d es q
```

Evaluated a value returns the value to the current continuation if there is one or pulls a continuation off the stack if there is not. If the stack is empty, nothing happens.

```
eval (State (Val v) d es q) = case d of
  Hole -> case es of
    (e:es') -> case e of
      (Val (Prompt p)) -> State (Val v) Hole es' q
      otherwise -> State (Val v) e es' q
    otherwise -> State (Val v) d es q
  otherwise -> State (ret d (Val v)) Hole es q
```

Evaluating `NewPrompt` places the value of the current prompt as the dominant term and increments the global prompt counter:

```
eval (State NewPrompt d es (Prompt p)) =
  State (Val (Prompt p)) d es (Prompt $ p+1)
```

# 4 | Translations

## $\lambda\mu$-to-DCC

The translation of a full program $M$ in the $\lambda\mu$-calculus to DCC is defined as $[\![M]\!]_p$ where the subscript $p$ denotes the translation is initialized with prompt $p$. Formally, this means that $[\![M]\!]_p \triangleq (\lambda p.\textsc{pp}\ p\ [\![M]\!])\textsc{np}$

**Definition 4.0.1** (Initialization of a translation of $M$ into DCC)

$$[\![M]\!]_p \triangleq (\lambda p.\textsc{pp}\ p\ [\![M]\!])\textsc{np}$$

**Definition 4.0.2** (Interpretation of $\lambda\mu$ into DCC)

$$\begin{array}{lcl} [\![x]\!] & \triangleq & x \\ [\![\lambda x.M]\!] & \triangleq & \lambda x.[\![M]\!] \\ [\![MN]\!] & \triangleq & [\![M]\!][\![N]\!] \\ [\![\mu\alpha.M]\!] & \triangleq & \textsc{wsc}\ p\ \lambda\alpha.\textsc{pp}\ p\ [\![M]\!] \\ [\![[\beta]M]\!] & \triangleq & \textsc{psc}\ \beta\ [\![M]\!] \end{array}$$

**Theorem 4.0.3** (Soundness of $[\![\bullet]\!]$) *If $M \to_\mu N$ then $[\![M]\!] \to_{DCC} [\![N]\!]$*

*Proof.* By induction on the definition of $\to_\mu$

$$
\begin{array}{lll}
(\mu\alpha.[\beta]M)N: & & (\alpha \neq \beta) \\
& [\![(\mu\alpha.[\beta]M)N]\!]_p & \\
\triangleq & [\![(\mu\alpha.[\beta]M)]\!][\![N]\!] & p \\
\triangleq & (\textsc{wsc}\ p\ \lambda\alpha.\textsc{pp}\ p\ [\![[\beta]M]\!])[\![N]\!] & p \\
\to_\beta & (\textsc{wsc}\ p\ \lambda\alpha.\textsc{pp}\ p\ [\![[\beta]M]\!]) & \Box[\![N]\!] : p \\
\to_\beta & (\lambda\alpha.\textsc{pp}\ p\ [\![[\beta]M]\!])(\Box[\![N]\!]) & \emptyset \\
\to_\beta & (\textsc{pp}\ p\ [\![[\beta]M]\!])\{\Box[\![N]\!]/\alpha\} & \emptyset \\
\to_\beta & \textsc{pp}\ p\ [\![[\beta]M]\!]\{\Box[\![N]\!]/\alpha\} & \emptyset \\
\to_\beta & \textsc{pp}\ p\ (\textsc{psc}\ \beta\ [\![M]\!])\{\Box[\![N]\!]/\alpha\} & \emptyset \\
\to_\beta & \textsc{pp}\ p\ (\textsc{psc}\ \beta\ [\![M]\!]\{\Box[\![N]\!]/\alpha\}) & \emptyset \\
\to_\beta & \textsc{psc}\ \beta\ [\![M]\!]\{\Box[\![N]\!]/\alpha\} & p
\end{array}
$$

$$
\begin{array}{lll}
(\mu\alpha.[\alpha]M)N: & & \\
& [\![(\mu\alpha.[\alpha]M)N]\!]_p & \\
\triangleq & [\![(\mu\alpha.[\alpha]M)]\!][\![N]\!] & p \\
\triangleq & (\textsc{wsc}\ p\ \lambda\alpha.\textsc{pp}\ p\ [\![[\alpha]M]\!])[\![N]\!] & p \\
\to_\beta & (\textsc{wsc}\ p\ \lambda\alpha.\textsc{pp}\ p\ [\![[\alpha]M]\!]) & \Box[\![N]\!] : p \\
\to_\beta & (\lambda\alpha.\textsc{pp}\ p\ [\![[\alpha]M]\!])(\Box[\![N]\!]) & \emptyset \\
\to_\beta & (\textsc{pp}\ p\ [\![[\alpha]M]\!])\{\Box[\![N]\!]/\alpha\} & \emptyset \\
\to_\beta & \textsc{pp}\ p\ [\![[\alpha]M]\!]\{\Box[\![N]\!]/\alpha\} & \emptyset \\
\to_\beta & \textsc{pp}\ p\ (\textsc{psc}\ \alpha\ [\![M]\!])\{\Box[\![N]\!]/\alpha\} & \emptyset \\
\to_\beta & \textsc{pp}\ p\ (\textsc{psc}\ \Box[\![N]\!]\ [\![M]\!]\{\Box[\![N]\!]/\alpha\}) & \emptyset \\
\to_\beta & \textsc{psc}\ \Box[\![N]\!]\ [\![M]\!]\{\Box[\![N]\!]/\alpha\} & p \\
\to_\beta & [\![M]\!]\{\Box[\![N]\!]/\alpha\} & \Box[\![N]\!] : p \\
\to_\beta & [\![M]\!]\{\Box[\![N]\!]/\alpha\}[\![N]\!] & p
\end{array}
$$
